ABSTRACT

The technique of lightening the shade of a person’s teeth is known as tooth whitening or tooth bleaching. For a variety of reasons, teeth can become discoloured, and whitening is frequently the preferred solution. Nowadays aesthetics play a major role in today’s lifestyle. One of the common procedures in cosmetic dentistry is bleaching of the tooth. There are many causes of tooth discoloration. According to the aetiology and localization it is divided into intrinsic and extrinsic causes. This review article tells us briefly about various aspects of tooth bleaching like causes of tooth discoloration, bleaching material and its mechanism, bleaching techniques and the adverse effect of bleaching. The walking bleach technique and in-office thermocatalytic bleach technique is non vital tooth bleaching techniques. Walking bleach method uses sodium perborate with distilled water while thermocatalytic bleaching uses hydrogen peroxide with heat. Extracoronal tooth bleaching techniques are in-office vital bleaching technique and at-home vital bleaching technique. There are number of adverse effects of tooth bleaching. Gingival irritation and tooth sensitivity are common side effects in vital tooth bleaching while root resorption, chemical burns is seen in non
vital bleach technique. Chemical burn can be avoided by application of petroleum jelly or Vaseline to gingiva and oral mucosa during bleaching. Gingival irritation is mainly seen in in-home vital bleach technique where the customized tray irritates the gingiva. This can be prevented by trimming the customized tray. Tooth sensitivity is also a common side effect of vital tooth bleaching.

Keywords: Tooth bleaching; bleaching techniques; adverse effects.

1. INTRODUCTION

Tooth discolouration is a common problem in various parts of the world [1-4]. The patients nowadays desire smiles that seem to be whiter and more beautiful. The media’s description of people with flawless white teeth has influenced the general population. Anterior teeth play important role in aesthetics of an individual mainly the colour of teeth and smile. Tooth discolouration gives an unaesthetic appearance to an individual especially on anterior teeth. Bleaching of tooth improves aesthetics by reducing tooth discolouration.

There are various studies which state that tooth discolouration is a common problem in various individuals of world and there is increase demand for tooth whitening treatment [1-4].

A study was conducted in United Kingdom on 3215 subjects [1]. About 50 percentage of population considered themselves to have tooth discoloration. He also concluded that there is rise in demand for tooth whitening treatment and cosmetic dentistry. A study on the female population of Saudi Arabia, result stated that about 43.7 percentage females had undergone tooth bleaching procedure and about 8.7 percent of females undergo bleaching procedure per year [2]. A study was conducted in city of Turkey at a dental school about 1014 individuals participated [3]. There were basic questions on demographic details along with questions regarding appearance of their tooth, dental treatment done on anterior, orthodontic treatment done on anterior teeth. The result stated that about 55.1% of the patients were not happy with the shade of their teeth, 29.9% had misaligned anterior teeth. The study also discovered that the most preferred dental treatment was bleaching of teeth in about 49 percent of cases. A study concluded that tooth discolouration is common in Chinese population and the people were not satisfied with colour of their tooth. This study used a colorimeter to measure the colour to upper central incisors in 405 adults and teenagers of Chengdu, China [4].

The earliest report of whitening for discoloured and non-vital teeth dates back to the 19th century [5]. In the ninth annual meeting of American Society of Dental Surgeons the first bleaching agent approved and recommended was chlorinated lime [6]. Other chemicals used were oxalic acid, chlorine solution, sodium hypochlorite, sodium peroxide [7-12]. 25% hydrogen peroxide in 75% ether can be used as a mixture for whitening of the teeth [13,14]. Harlan first reported the use of hydrogen peroxide for bleaching of teeth in research article named “The Removal of Stains From the Teeth Caused by the Administration of Medicinal Agents and the Bleaching of Pulpless Teeth” in 1884 [15]. In 1981 Abbot suggested to use 30 percentage of hydrogen peroxide i.e. superoxol for whitening of the teeth [16]. To accelerate the bleaching process many authors suggested to used heat along with bleaching agents [17]. Heated solution of sodium perborate and superoxol was recommended for whitening of teeth by Prinz in 1924 [18].

Mainly the intrinsic colour and extrinsic stains influence the colour of the teeth [19,20]. Scattering and absorption properties of enamel and dentin play important role in intrinsic colour of the tooth [21,22]. Extrinsic stains are seen on tooth where there is less access to tooth brushing and abrasive action of toothpaste. These extrinsic stains are increased by habit like smoking, tannin rich food like red wine [23]. Extrinsic stains can be caused by occupational exposure to metallic salts or due to medicines containing metal salts [23]. There are various treatment modalities to treat tooth discoloration we can use whitening tooth pastes, stains can be removed by scaling and polishing, bleaching of teeth [24]. Various bleaching include agent are hydrogen peroxide, carbamide peroxide, sodium perborate, oxalic acid and chlorine solution [7-12]. There are organic and inorganic peroxides. Peroxides are powerful oxidizers and effective bleaching agent [25].
Bleaching is divided into intracoronial and extracoronial bleaching. Intracoronial bleaching is done on non-vital teeth while extracoronial bleaching is done on vital teeth. Thermocatalytic bleaching is a best intracoronial bleaching technique which uses hydrogen peroxide and heat [26,27]. Extracoronial bleaching uses a chemical on the outer surface of a tooth to remove discolouration from vital teeth. Fig. 1 tells us about the classification of various bleaching techniques.

There are certain disadvantages of using the bleaching agent in the oral cavity. The main disadvantage of bleaching of vital tooth is sensitivity, gingival irritation. A study was conducted to assess the risk of using bleaching agents [28]. The result stated that 50.3% of individuals experienced sensitivity after at-home bleaching and 39.3% after in-office bleaching. While gingival irritation is seen in 14% of cases after in-home bleaching and in-office bleaching about 35.7% individuals suffered from gingival irritation. This review article gives a brief overview of bleaching of teeth which includes causes of tooth discoloration, various bleaching agent, and their mechanism of action, bleaching procedures and its adverse effects.

2. CAUSES OF TOOTH DISCOLOURATION

It is very important to diagnose the causes of tooth discoloration as it will affect the treatment modality. Therefore it's important for a dentist to know about the aetiology of tooth discoloration for diagnosis and arriving at proper treatment plan [19]. The causes of tooth discoloration are divided into intrinsic, extrinsic or combination of the both causes [29].

2.1 Extrinsic Causes

The cause for intrinsic staining is the deposition of chromogenic substance on the surface of external tooth surface. These chromogenic substances are seen in tea, coffee, tobacco, oranges, carrots, licorice, chocolate [19,23,29]. It is also seen in tannin rich products like red wine. Metal salts in mouthwashes cause extrinsic discoloration of teeth. Dental plaque can also cause extrinsic staining. Nathoo et al in 1997 gave the classification for extrinsic tooth discoloration [23]. He has classified extrinsic tooth discoloration under three categories. These categories are N1 type, N2 type and N3 type. In N1 type the chromogens or the colour substance stick to tooth surface and causes discoloration but the stain is of the same colour as the chromogen. In N2 type, here there is change in chromogen colour after sticking to tooth surface. Colourless prechromogens bind to external surface of tooth and a chemical reaction occur between tooth and prechomogens to form a stain. Extrinsic stains can be removed easily as they are found on tooth surface. Stronger the bonding of chromogens to tooth surface stronger is the extrinsic stain. Attractive forces include van der...
waals force, electrostatic force, hydration forces, hydrophobic interactions, dipole-dipole forces and hydrogen forces [30]. These attractive forces strongly bind the chromogens to tooth. In a study it showed that with ageing the stains of tea and coffee are difficult to remove. The first classification of extrinsic stains was based on metallic and non-metallic stains [31]. This classification could not explain the mechanism of staining and tooth are not stained by all metals. Therefore there was a need for a newer classification which was given by Nathoo which was based on chemistry of staining.

2.2 Intrinsic Causes

2.2.1 Pulp necrosis

Irritation to dental pulp by microbial, chemical or mechanical stimulus which may leads to tooth necrosis. This releases toxic substances which penetrate dentinal tubules and causes discolouration of surface dentin leading to intrinsic staining of tooth. Discolouration is directly proportional to the time the discolouring agent stays on the tooth surface. Longer the discolouring agent stays in contact with tooth surface stronger is the discolouration [25,32].

2.2.2 Intrapulpal hemorrhage

Intrapulpal bleeding occurs due to severe and sudden trauma to tooth. This bleeding is caused by rupture of blood vessels. The blood component flows in the dentinal tubules which leads to discolouration [33]. First the tooth colour changes to pink then there is breakdown of red blood cells into heme and globulin. Then heme reacts with the putrefying pulpal tissue to form iron [19]. Then the iron converts hydrogen sulphate into iron sulphate. Iron sulphate stain the tooth in grey colour and get deposited deep in the dentinal tubules causing discolouration of teeth.

2.2.3 Coronal filling materials

Old composite restoration can cause discolouration of tooth due to microleakage. Amalgam restoration can lead to greyish discolouration of dentinal surface. When amalgam restoration are used in lingual access opening preparation in premolar or developmental grooves in anterior teeth in this amalgam can cause discolouration. This discolouration is difficult to manage as there is recurrence of discolouration in this. Sometimes amalgam restoration, the metal post gives darker appearance to tooth due to transparency of enamel enamel. This can be also caused by release of metallic ions from restoration [25].

2.2.4 Root resorption

Root resorption is clinically has no symptoms but pinkish spot can be seen at cementoenamel junction. This should be known to distinguish between discoulouration and root resorption [19].

2.2.5 Dystrophic calcification

At the time of ageing there is deposition of secondary dentin which results in darkening of tooth surface. This is mainly due to the light transmitting properties of tooth [19].

3. BLEACHING AGENTS

Bleaching agents are used for whitening of the discoloured tooth. The first used bleaching agent is chlorinated lime [6]. Commonly use bleaching agents are hydrogen peroxide, carbamide peroxide and sodium perborate [7-12].

3.1 Hydrogen Peroxide

Hydrogen peroxide is an active substance in the bleaching agents. It is a colourless solution which is highly dissolving in water to give acid solution. It is used as a bleaching or whitening agent for tooth, balancing agent in wine preparation, disinfection of seeds and in treatment of water [34].There are organic and inorganic peroxides. Peroxides are strong and powerful oxidizing agents and are considered as the by product of hydrogen peroxide. When hydrogen is replaced with metal it forms inorganic peroxide, when replaced with organic radical it forms organic peroxide [25]. At low concentration it is used as a bleaching agent. At higher concentration it is highly unstable and can explode if not kept at cooler temperature.

3.1.1 Mechanism of action

Hydrogen peroxide can penetrate the dentinal tubules as it has less molecular weight. Then it releases oxygen molecules that break the double bond of inorganic and organic substance present in dentinal tubules [35]. If along with hydrogen peroxide heat is used it will fasten the process [36].

3.2 Sodium Perborate

Sodium perborate is an effective whitening agent which is sold in powder form. It is highly stable in
powder. It is safe and easy to control bleaching agent [37].

3.2.1 Mechanism of action

Sodium perborate in powder form when react with water or acid it breaks into sodium perborate, hydrogen peroxide and nasan oxygen molecule. The nasan oxygen molecule breaks the double bond present in dentinal tubules and treats discolouration of tooth [37].

3.3 Carabamide Peroxide

Carabamide peroxide is a compound formed by urea and hydrogen peroxide. It is pure white in colour and is organic substance it is called as urea hydrogen peroxide. In water it breaks into 3% hydrogen peroxide and 7% urea. It is used along with glycerine to make the substance more stable. The most common concentration of carabamide peroxide is 10 percent. This 10 percent of carabamide peroxide is more effective than 0.2 percent chlorohexidine [38].

3.3.1 Mechanism of action

Carabamide peroxide is highly soluble in water. When reacts with water gives urea, ammonia, carbon dioxide and hydrogen peroxide. Hydrogen peroxide releases nasan oxygen and breaks the double bond in dentinal tubules [38].

4. BLEACHING PROCEDURES

Tooth bleaching procedures are divided into intracoronal and extracoronal bleaching. The intracoronal bleaching is also known as bleaching of endodontically treated tooth or non vital bleaching. The intracoronal bleaching is further divided into walking blech technique and in office thermocatalytic blech technique. The extracoronal bleaching is the vital tooth bleaching. The extracoronal bleaching is divided into in-office vital bleach technique and in-home bleach technique [39]. Fig. 1 gives the classification of bleaching technique.

4.1 Intracoronal Bleaching Technique

4.1.1 Walking blech technique

Article regarding walking bleach technique was first given by Salvas et al. the technique uses sodium perborate along with distilled water [40]. Further nutting and poe used hydrogen peroxide instead of water to accelerate and increase the effect of bleaching agent [41]. The combination of sodium perborate and distilled water is used even nowadays and is one of the most effective and successful procedure for intracoronal bleaching [37]. In a studies done by E A Aldecoa et al, he treated 534 discoloured teeth by tetracycline over a span of years and intracoronal bleaching was proved effective and successful 68.

4.1.1.1 Procedure [39]

Tooth is prepared for whitening procedures by cleaning it with prophylactic pastes to remove debris. Petroleum jelly is applied to gingival tissue and oral mucosa near the tooth to be bleached. To avoid direct contact to oral mucosa due to chemicals in bleaching agent. Apply rubber dam. Access opening is re-established. Root canal filling material is removed with plunger or gates glidden drill up to a level of alveolar bone. Rest of filling material is compressed at level 1 mm apical to cementoenamel junction which is confirmed by periodontal probe. Now seal the opening of root canal with 1 mm intracoronal barrier to avoid perforation of bleaching agent. Glass ionomer cement, resin modified glass ionomer cement and mineral triaggregate can be used as a barrier. It is important to seal the bleaching agent to crown itself and prevent its entry to area apical to level of bone as it causes cervical root resorption. Cover the patient’s eyes and face with protective equipments and the operator should wear gloves. Sodium perborate and distilled water is mixed in thick paste. The thick mixture of sodium perborate and distilled water is carried to pulp chamber with a plastic instrument. The facial surface should be in contact with the thick paste for bleaching to be effective. A small cotton pellet containing hydrogen peroxide is placed over the mixture. Now seal the access opening with thick adhesive or temporary restoration about 3 mm in thickness. This will create a seal and prevent leakage of bleaching agent. The bleaching effect is seen in 24 hours after the procedure. Patient should return to dentist after a week for evaluation of the result.

4.1.2 In-office thermocatalytic bleach technique

In thermocatalytic bleaching heat is used along with the chemicals. This is the best technique to bleach non vital tooth due to strong interaction between hydrogen peroxide and heat [26]. Electric heating devices are used for heat
application. The additional heat application increases the whitening properties of hydrogen peroxide. Heat can also be applied by heated metallic instrument. The reaction releases more nasant oxygen when heat is applied [39].

4.1.2.1 Procedure

As discussed in the procedure of walking bleaching technique the same technique will be used that involves cleaning tooth with prophylactic procedure, applying Petroleum jelly, use of rubber dam, access opening is re-established and root canal filling material is compressed till the the level of cementoenamel junction. But in this technique it involves the use of 30-35 percent of hydrogen peroxide in pulp chamber which is followed by heat application. There is usually 5-6 minutes of exposure to tooth and solution is replenished frequently. Pellet of cotton containing hydrogen peroxide is placed in the pulp chamber and sealed with temporary restoration till next appointment.

In-office themocatalytic bleaching method is very good when the walking bleach technique fails or when walking bleach technique doesn’t give effective results even after 3-4 times application [42].

4.2 Extracoronal Bleaching Technique

4.2.1 In-office vital bleach technique

In this technique high concentration of hydrogen peroxide is used. The concentration of hydrogen peroxide is about 30-35%. In this procedure the dentist has full control over the procedure and can stop when the desired shade is achieved. Before the use of chemicals the surrounding gingiva and oral cavity should be covered by rubber dam. This can also be activated by heat for an hour in dental clinic [43].

4.2.1.1 Procedure [39]

Radiograph is taken to see the presence of decay, faulty restoration and the location of pulp horn.

The tooth shade is evaluated by shade guide and photos before and along the procedure. Vaseline is applied to gingival tissues surrounding to tooth to be bleached. Protective equipments are worn by patient and dentist, and rubber dam is applied. With the help of cotton hydrogen peroxide is applied to the labial surface of tooth.

Heat is applied by electric heating device. The temperature should be maintained at 52-60 degree Celsius. The time of treatment should not exceed more than half an hour even if treatment is not effective. The heating source is removed and teeth are allowed to cool down for 5 minutes. Then the teeth are cleaned thoroughly to remove the bleaching agent then the teeth are dried. Neutral sodium fluoride gel is used for 2-5 minutes. Patient is told used to fluoride rinse foe about 14 days.

4.2.2 In-home vital bleach technique

It uses less concentration of bleaching agent i.e. 10-20 percentage carbamide peroxides10. The concentration of 10 percent of carbamide peroxide is used for 8 hours per day while concentration of 15-20 percent is used for about 3-4 hours. The procedure is carried out by the patients but is done in supervision of dentist at the time of recall. A custom made mouth guard is fabricated by dentist and the bleaching solution is applied on it and is worn by patient at night for about 14 days [43].

4.2.2.1 Procedure [39]

At the first appointment maxillary and mandibular impression are taken by alginate. The base of caste should be trimmed for better adaptation.

Reservoirs can be placed on the labial surface of tooth for bleaching agent to be applied properly to the tooth surface. The reservoirs are made by wax and it should be 1 mm short of free gingival margin. Material used to fabricate the tray is thick semi rigid plastic material. The adaptation of the tray should be checked properly in the second appointment and should be trimmed if any problem. The patient is instructed to brush the teeth prior to use tray and patient is instructed to use sufficient amount bleaching agent to cover the labial surface of tooth. For every session the tray should be worn for about 4 hours. The patient should maintain proper and regular follow up with the dentist for evaluation of bleaching procedure.

5. ADVERSE EFFECTS OF BLEACHING

5.1 Adverse Effect of Intracoronal Bleaching

5.1.1 External root resorption

External root resorption is one of the disadvantage of intracoronal bleaching. Four
cases of root resorption were reported after intracoronal bleaching procedure with heat by Harrington and Natkin where the pulp was devital [44]. More such cases are reported by Lado et al which also developed cervical root resorption followed after intracoronal bleaching procedure [45].

5.1.2 Chemical bur

Chemicals used in the bleaching procedures are caustic in nature and can cause chemical burn. The chemical burn is caused when there is interaction of chemicals with gingiva or oral mucosa surrounding tooth to be bleached. To prevent this petroleum jelly is used [39].

5.1.3 Inhibition of resin polymerization

The nascent oxygen liberated after the bleaching procedure affects the bonding and polymerisation of composite resin [39].

5.2 Adverse Effect of Extracoronal Bleaching

5.2.1 Tooth sensitivity

Tooth sensitivity is the most common side effect of extracoronal bleaching. The tooth sensitivity after vital tooth bleaching is seen in about 50 percent of cases [46]. The tooth sensitivity occurs after the procedure and is persistent for about 2-3 days. Mainly the sensitivity is maximum on the third day as the pulp has maximum saturation of oxygen [47]. Tooth sensitivity does not depend on the patient's age, sex, fault restoration while it depends on patient who change the bleaching agent more than once a day.

5.2.2 Enamel damage

Extracoronal bleaching can cause damage to enamel. Damage is caused by erosive action of bleaching agent. The enamel is made weak by extracoronal bleaching technique mainly due to three reasons. The first reason include mineral loss as the ratio of organic and inorganic changes. The second reason includes change in enamel surface morphology and the third reason is alteration of enamel micro hardness, many in vitro studies are done on enamel [48,49].

5.2.3 Gingival irritation

Gingival irritation is the most common side effect of extracoronal bleaching procedure. Gingival irritation can occur with or without tooth sensitivity often patient has difficulty in distinguishing both. In in-home vital bleaching technique, gingival irritation can take place due poorly fitting or ill fitting trays but this can be corrected by trimming the tray [50]. In in-office bleaching technique, gingival irritation takes due to faulty gingival barrier protection [43,51].

5.2.4 Effect on restoration

In the teeth with amalgam restoration extracoronal bleaching is difficult to perform as there is release of mercury from the amalgam restoration [52,53]. Mercury with many disadvantage on health so it is advised to avoid bleaching on amalgam restoration. Studies state that bleaching affects the chemical and physical properties of restorative material like its strength the bound to tooth structures, marginal leakage, and release of ions.

6. CONCLUSION

Tooth Bleaching is a procedure to lighten the shade of the tooth. Nowadays people of world are focusing more on aesthetics and there is growing demand for tooth bleaching procedures. There are number of aetiology’s for tooth discolouration which are divided into intrinsic and extrinsic causes. Intrinsic causes are mainly microbial cause, trauma to tooth, non vital tooth. Extrinsic causes are due to tea, coffee, wine, tobacco. Bleaching agents are hydrogen peroxide, carbamide peroxide and sodium perborate. The bleaching procedures are vital tooth bleaching procedure and non vital bleaching procedures. There are various adverse effects of tooth bleaching like gingival irritation, tooth sensitivity, cervical root resorption, damage to enamel, damage to restorative materials, chemical burns.
